The uncertainty in the calculation of atmospheric neutrino fluxes is studied. The absolute value of atmospheric neutrino fluxes is sensitive to variation of the primary cosmic ray flux model and/or the interaction model. However, the ratios between different kind of neutrinos stay almost unchanged with these variations. It is unlikely that the anomalous ratio $(\nu_\mu/\nu_e)_{obs}/(\nu_\mu/\nu_e)_{MC}$ reported by Kamiokande and Super Kamiokande is caused by the uncertainty of predicted atmospheric neutrino fluxes.

1. Introduction

After the discovery of an anomalous ratio of ν_e/ν_μ in the atmospheric neutrinos by Kamiokande, refined calculations of atmospheric neutrino fluxes have been made intensively by several authors[1][2][3][4][5]. The differences between different authors have been compared in Ref. [6]. The major differences are in the primary cosmic ray flux and in the hadronic interaction model. These are also the main sources of uncertainty in the calculation of atmospheric neutrino fluxes.

There have been many measurements of the primary cosmic ray flux, but they do not agree with each other. We have to consider this disagreement as the uncertainty of the primary cosmic ray flux. There also have been many experimental studies of hadronic interactions. However, the most important piece of information, the energy spectrum of secondary particles in the projectile region, is not well known enough for an accurate calculation of atmospheric neutrino fluxes. This is partly because, as high energy physics experiments moved to the colliders, this measurement has become more difficult to make.

Adding to the above, the density structure of the atmosphere is a potential source of uncertainty. In many calculations, the US standard is often used as the 'standard' model. However, it is also known that the atmospheric density structure has a latitude dependence and seasonal variations.

In this paper, we study how these uncertainties affect the atmospheric neutrino calculation in the energy range of $\lesssim 10$ GeV based on Ref. [5](HKKM). Note we use the one-dimensional approximation as HKKM throughout this paper.

2. Variation of calculation Model

2.1. Primary cosmic ray flux

In Fig. 1 are shown the observations of cosmic ray protons at $< 10^4$ GeV by different groups. We consider 3 flux models in this study: high, mid, and low shown in the figure for solar min. The flux models for primary cosmic rays agree in $\lesssim 5$ GeV region, where the differences are small except for those caused by solar modulation.

Cosmic rays above a few 100 MeV originate in Galactic space. When they enter the solar sphere, they are pushed back by the solar wind. As this effect is more pronounced for lower energy cosmic rays, the energy spectrum of low energy cosmic rays varies with the strength of the solar wind, or with the solar activity. However, this modulation is expected to be around 5% from the minimum to the maximum of solar activity at 10 GeV. Above this energy, the effect of solar activity on the cosmic ray flux is very small.

The variation due to solar activity in the $\lesssim 10$ GeV region agrees well with the expectation based on the Mid-flux model and conventional solar modulation formulae. The exception in Fig. 1 is the crosses which are the base data for the high

Figure 1. Observed cosmic ray proton flux. Crosses from Ref. [7], open upward triangles stand for LEAP[9], open squares for MASS[8], open downward triangles for IMAX[10], open vertical diamonds for CAPRICE[11], and open horizontal diamonds for BESS[12]. pluses, closed squares, closed vertical diamond, closed upward triangles, and closed downward triangles are from Refs[22],[26],[25],[34],[35],[36], and [38] of HKKM respectively.

flux model. We consider that the uncertainty in primary cosmic ray flux is small for $\lesssim 10$ GeV.

Above 10 GeV, there are rather large differences among the different experiments. This may be caused by the inherent difficulties in making the measurements. Particularly, the problems in the estimation of instrumental efficiency and limited exposure time in balloon experiments. At this moment we have to assume that there are large uncertainties in the primary cosmic ray flux measurements in the $\gtrsim 10$ GeV region. However, it is interesting that recent experimental values with super conductive magnetic spectrometers distribute rather around the Low flux model.

It is noted that around 20% of nucleons are carried by nuclei heavier than the proton. We do not show the details but for the heavier nucleus

cosmic rays we use the flux value of HKKM.

Even using the one dimensional approximation, the geomagnetic field affects the calculation of atmospheric neutrino fluxes through the primary cosmic ray flux due to the geomagnetic cutoff. Principally, however, the geomagnetic cutoff is not a source of uncertainty since it can be calculated to very good accuracy from the measured geomagnetic field.

2.2. Hadronic interaction

In the calculation of the atmospheric neutrino fluxes, hadronic interaction Monte Carlo code is one of the most important components. However, there are uncertainties in the hadronic interaction model, due to the lack of suitable experimental data. The interaction models used by different calculations are slightly different to each other.

A comparison of the secondary particle momentum spectrum is shown in Fig. 2 and in Fig. 3 for several Monte Carlo codes which have been used in the calculation of atmospheric neutrino fluxes. (This figure is taken from Ref. [6]). The variable x used in the figure is defined as $x = P_{\text{secondary}}/P_{\text{incident}}$. It should be noted that the difference between the histograms (BGS[2] and HKHM[3]) and the smooth curve (BN[1]) is not so large as it appears. Since each value is multiplied by the variable x , their differences are emphasized in the low x region.

It is generally difficult to modify an established hadronic interaction Monte Carlo code due to the energy momentum conservation and to the correlation of secondary particles. However, in the case of the atmospheric neutrinos, the correlations are not important. We use an ‘inclusive’ hadronic interaction Monte Carlo code for the study of the variation of hadronic interactions.

The calculation of atmospheric neutrino fluxes with the inclusive interaction code is similar to the analytic calculation. In the case of the analytic calculation, however, it is difficult to treat the competition process between decay and interaction for hadronic particles. This is the most crucial point in the analytic calculation. Therefore, we make the Monte Carlo study with the inclusive hadronic interaction code in this paper.

Starting with the hadronic interaction model of

Figure 2. Secondary π^+ energy spectrum calculated using the interaction model used by various different authors (taken from Ref. [6]).

FRITIOF 1.6 and Jetset 6.3, we consider ‘moderate’ variations from that. The variation of secondary particle energy spectrum is created as follows: denoting a ‘starting’ energy spectrum of secondary particles as

$$\frac{dN}{dx} = f_{ptl}(x) ,$$

where we take $x = E_{2nd}/E_{inc}$ and E is the kinetic energy. Moderate variation to this secondary particle energy spectrum can be made with a parameter α as

$$\frac{dN}{dx} = A(\alpha) f_{ptl}(x^{1+\alpha}) ,$$

where $A(\alpha)$ is a factor introduced for energy conservation as:

$$A(\alpha) = \frac{\int x f_{ptl}(x) dx}{\int x f_{ptl}(x^{1+\alpha}) dx} .$$

In other words, we request that the energy sum for each kind of particle is conserved. This modification method works efficiently to vary the slope of the secondary particle spectrum at $x \approx 0.3$.

Figure 3. Secondary π^- energy spectrum calculated using the interaction model used by various different authors (taken from Ref. [6]).

This modification also changes the number of particles for each kind of secondary particle ($= \int x f_{ptl}(x) dx$). The variation of $\alpha = \pm 0.1$ roughly corresponds to ± 10 % variation at $x = 0.3$, and to a ± 20 % variation of the multiplicity. The variation of α from -0.2 to $+0.2$ is considered in this paper. The variation limit of α is set as 2 times of the possible uncertainty of multiplicity (± 10 %) in the hadronic interaction.

Examples of this modification are shown in Fig. 4 and Fig. 5 for $p+air \rightarrow \pi^\pm$ at $E_p = 32$ GeV with the secondary particle spectrum of BN at ≈ 20 GeV from Ref. [6] for comparison. One may notice that the secondary particle spectrum of BN is outside of our variation limit, even considering the difference of incident particle energy. To include BN secondary energy spectrum, probably a different starting point is needed.

In addition, variations of inelastic cross-sections from -20 % to $+20$ % and k/π -ratio from -40 % to $+40$ % are also considered. Note that we have assumed the same α for all kinds of secondary particles, although $f_{ptl}(x)$ is different for each particle, and σ_{inel} varies at the same ratio for all hadronic interacting particles. The

Figure 4. Secondary π^+ energy spectrum from FRITIOF 1.6 and Jetset 6.3 at 30 GeV with its variations for $\alpha = \pm 0.2$. For comparison, that of BN at ≈ 20 GeV is also shown.

variation range considered here is larger than the uncertainty normally considered[13].

2.3. Density structure of the atmosphere

For the density structure of the atmosphere, the US-standard atmosphere model is often used. However, since we are interested in the effect of the variation of atmospheric structure, we introduce a simple model with a single scale height. The air density is expressed as a function of height as:

$$\rho = \frac{\rho_{col}}{h_0} \exp\left(-\frac{h}{h_0}\right).$$

For the ‘standard’, we take $\rho_{col} = 1.231 \text{ kg/m}^3$ and $h_0 = 8.4 \text{ km}$, such that it agrees with the US-standard in global features.

We study the effect of variations from -10% to $+10\%$ both in the scale height and in the column density. However, when we study the variation of interaction model only, we use the US-standard atmosphere model.

3. Variation of neutrino fluxes

We have summarized the variation of atmospheric neutrino fluxes for the model variations of primary cosmic ray flux (Fig. 6), hadronic interaction (Fig. 7), and atmospheric density structure (Fig. 8).

From these figures, one can see that the variation of the primary cosmic ray flux and the secondary particle spectrum in the hadronic interactions have a large effect on the atmospheric neutrino fluxes. However, the variation of other hadronic interaction parameters and the density structure of atmosphere have far smaller effect on the atmospheric neutrino fluxes.

Shown in Fig. 9 is the variation region of the ratios among different kinds of neutrinos, with all the variations considered here. It is seen that the variation of the ratios is very small. All of the $(\bar{\nu}_e + \nu_e)/(\bar{\nu}_\mu + \nu_\mu)$ variations are inside of the boundary of $\pm 5\%$ at 1 GeV. However, the small statistics make the ratio variation larger in the $\gtrsim 3 \text{ GeV}$ region due to Monte Carlo method.

Figure 6. The variation of atmospheric neutrino fluxes due to the change of primary cosmic ray model. The ratio to that with Mid primary flux model (HKKM) is shown. For the flux models, see the text in section 2.1.

We have also depicted the $(\bar{\nu}_e + \nu_e)/(\bar{\nu}_\mu + \nu_\mu)$ ratio by HKKM shifted by a factor $1.54 = 1/0.65$. Note that SuperKamiokande have observed the ratio $(\nu_\mu/\nu_e)_{obs}/(\nu_\mu/\nu_e)_{MC} \approx 0.65$ both for sub-GeV and multi-GeV regions.

4. Summary and comments

We have studied the effect of variation in primary cosmic ray flux, hadronic interaction model, and density structure of atmosphere on the atmospheric neutrino fluxes. The variation of the primary cosmic ray flux is directly related to the absolute value of atmospheric neutrino fluxes. The secondary particle spectrum in the hadronic interactions also strongly affects the absolute value of the fluxes. Other variations considered here do not have a large effect on the atmospheric neutrino fluxes.

Variation of primary cosmic ray flux and/or interaction model does not cause a large change in the ratio of different kinds of neutrino. We have noted that the secondary particle spectrum of BN

Figure 7. The variation of atmospheric neutrino fluxes due to the variation of interaction model. The ratio to the HKKM neutrino fluxes is shown. For the parameters used in the figure, see the text in section 2.2.

is outside of our variation limit. This may be the case for the interaction model used by different authors. However, the ratio $(\bar{\nu}_e + \nu_e)/(\bar{\nu}_\mu + \nu_\mu)$ does shows a good agreement among different authors (See the comparison in HKKM). Probably a variation from a different starting point would not give a very different answer. Thus, it is difficult to explain the ratio $(\nu_\mu/\nu_e)_{obs}/(\nu_\mu/\nu_e)_{MC}$ observed in Kamiokande and SuperKamiokande by the uncertainty in the calculation of atmospheric neutrino fluxes.

However, when applying the calculated atmospheric neutrino fluxes to the neutrino oscillation study, the absolute values of the fluxes become important. The determination of cosmic ray flux to a high accuracy and the detailed study of hadronic interaction at $x = E_{2nd}/E_{inc} \approx 0.3$ are crucial.

The uncertainty for the arrival direction was not discussed so far in this paper. We shortly comment on the effect of the muon bending by geomagnetic field and transverse momentum in

Figure 8. The variations of atmospheric neutrino fluxes due to the variation of atmospheric model. The ratio to the ‘standard’ model is shown. For the parameters used in the figure, see the text in section 2.3

the hadronic interaction. For the muon in the geomagnetic field, we can calculate the average bending angle before decay as:

$$\begin{aligned}\theta &= c\gamma\tau_\mu/r_G = \frac{cE_\mu\tau_\mu}{m_\mu} / \frac{E_\mu}{c \cdot eB} = c^2 \cdot \frac{eB}{m_\mu} \cdot \tau_\mu \\ &= (3 \times 10^8 \text{ (m/sec)})^2 \frac{B(\text{T})}{106 \times 10^6 \text{ (eV)}} 2.2 \times 10^{-6} \text{ (sec)} \\ &= 0.19 \times 10^4 B(\text{T}) .\end{aligned}$$

Therefore, the bending angle for the typical geomagnetic field ($\approx 0.5 \times 10^{-4}$ T) is around 0.1 radian or 5 degree. This is probably not an urgent problem at this moment.

We note that the typical value of the transverse momentum in a hadronic interaction is ~ 0.3 GeV. Therefore, the transverse momentum is unimportant for $\gtrsim$ a few GeV.

Acknowledgements. The author is grateful to S. Orito for showing the BESS data in Fig. 1,

Figure 9. Variation of ratios among different kinds of neutrino with all the variation considered in sections 2.1–2.3 in all the combinations. The dashed line shows the ratio $(\bar{\nu}_e + \nu_e)/(\bar{\nu}_\mu + \nu_\mu)$ of HKKM shifted by a factor of $1.54 = (1/0.65)$.

and J. Holder for his careful reading of the manuscript. He thanks to T.Kajita, K. Kasahara, and S. Midorikawa for the collaboration, and T.K. Gaisser for the communications.
